Edited by T. C. Lubensky, University of Pennsylvania, Philadelphia, PA, and approved January 24, 2012 (received for review November 22, 2011)

Colloidal systems find important applications ranging from fabrication of photonic crystals to direct probing of phenomena typically encountered in atomic crystals and glasses. New applications—such as nanoantennas, plasmonic sensors, and nanocircuits—pose a challenge of achieving sparse colloidal assemblies with tunable interparticle separations that can be controlled at will. We demonstrate reconfigurable multiscale interactions and assembly of colloids mediated by defects in cholesteric liquid crystals that are probed by means of laser manipulation and three-dimensional imaging. We find that colloids attract via distance-independent elastic interactions when pinned to the ends of cholesteric oily streaks, line defects at which one or more layers are interrupted. However, dislocations and oily streaks can also be optically manipulated to induce kinks, allowing one to lock them into the desired configurations that are stabilized by elastic energy barriers for structural transformation of the particle-connecting defects. Under the influence of elastic energy landscape due to these defects, sublamellar-sized colloids self-assemble into structures mimicking the cores of dislocations and oily streaks. Interactions between these defect-embedded colloids can be varied from attractive to repulsive by optically introducing dislocation kinks. The reconfigurable nature of defect-particle interactions allows for patterning of defects by manipulation of colloids and, in turn, patterning of particles by these defects, thus achieving desired colloidal configurations on scales ranging from the size of defect core to the sample size. This defect-colloidal sculpturing may be extended to other lamellar media, providing the means for optically guided self-assembly of mesoscopic composites with predesigned properties.

Topological defects play an important role in determining material properties, mediating phase transitions, and causing numerous irreversible phenomena (1–6). For example, dislocations—line defects in periodically ordered materials—impart malleability to solids such as metals and thus are of great practical utility. Liquid crystals (LCs), soft materials with long-range orientational but only partial or no positional order (1, 7), are often employed as model systems to study defect-related phenomena in fields ranging from early universe cosmology (8) to condensed matter (9, 10). For example, lamellar media are often studied using the model system of a cholesteric LC in which the constituent chiral molecules locally align along a common direction called “director” $\mathbf{n}(\mathbf{r})$ that twists around a helical axis to form a twist-periodic structure (7, 11–13). When spatial distortions of the equilibrium twisted structure are on a scale much larger than the helical periodicity, this one-dimensionally periodic system exhibits elastic properties similar to those of layered systems such as smectic LCs (7, 11). Molecular, atomic, or spin configurations periodic in one direction have many similar properties and are encountered in a multitude of other condensed matter systems, such as helimagnets (13), various smectic phases of LCs (1, 10), water-surfactant mixtures (14, 15), block-copolymers (16), colloidal assemblies (17), lipids (18), DNA condensates (19), etc. These media are of great interest from the standpoint of controlling their

bulk elastic and optical properties by stabilizing and decorating networks of defects with particles (20–22). A number of studies of colloids in LCs have revealed how their properties are enriched by presence of defects (20–33). The fascinating richness of interactions involving colloids and defects in lamellar systems (14, 20, 21, 27, 28, 32, 33) and their potential practical applications require that these effects be explored on the level of individual particles and defects.

In this work, we probe defect-particle interactions and show that colloidal stabilization of defect structures can be extended to individual defect-particle level. Because the nature and strength of these interactions are defect-dependent, we use three-dimensional (3D) optical imaging based on fluorescence confocal polarizing microscopy (FCPM) (34) and two-photon excitation fluorescence polarizing microscopy (2PEF-PM) (35) (Fig. S1) to visualize the internal defect core structures and layer deformations. We optically generate various defects and alter their internal structure via noncontact manipulation with laser tweezers and then quantitatively probe the ensuing particle-defect and particle-particle interactions. We demonstrate the feasibility of forming predesigned stable 3D configurations of colloidal particles arranged along defects within cholesteric layers as well as along directions perpendicular to the layers. This may enable the physical “synthesis” of novel composites having optically controlled properties, with patterned defect lines playing the role of artificial bonds between colloids and providing a framework for testing various elastic theories. We also demonstrate the ability to pattern sublamellar-sized particles within the defect cores, which is of great interest for nanophotonics applications.

Colloidal Interactions Mediated by Topologically Unstable Defect Clusters

Cholesteric LCs host a great variety of linear defects that are also encountered in other lamellar systems (1, 2). The most abundant of these defects are dislocations and oily streaks that terminate or interrupt one or more layers (10). Elementary edge dislocations have Burgers vector $|\mathbf{b}| = b = p/2$ (where p is the cholesteric pitch, the distance along the helical axis over which $\mathbf{n}(\mathbf{r})$ twists by 2π) (Table S1). Their cores comprise a dipole of λ - and τ -disclinations of opposite half-integer strength.* An elementary oily

*In the λ disclinations, the material \mathbf{n} -director field is non-singular because of \mathbf{n} being parallel to the defect line in its core, so that the singularity is observed only in the immaterial director fields χ (along the helical axis) and τ orthogonal to both \mathbf{n} and χ . In the τ -disclinations, the τ field is non-singular but \mathbf{n} and χ director fields are singular. In χ -disclinations, the singularities are found in both \mathbf{n} and τ director fields but not in the χ field (10).

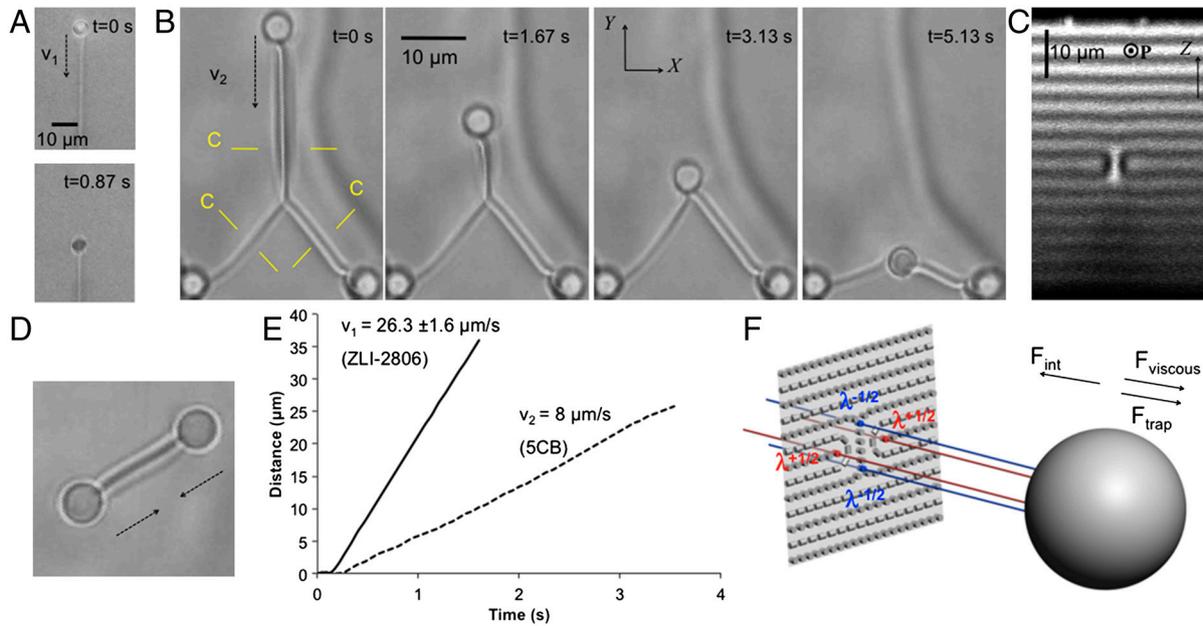

Fig. 1. Defect–particle interaction mediated by a Lehmann cluster. (A) A defect cluster in a cholesteric LC (ZLI-2806 and CB15) terminates at a particle and can be stretched by optically translating it but contracts once the colloid is released from the trap. (B) A Lehmann cluster in a cholesteric LC (5CB and CB15) is manipulated with the help of an optically trapped particle so as to form a node of clusters. Upon turning the trap off, the particle returns to its original position along the defect line between two stationary trapped colloids, as seen in the frames marked with elapsed time. (C) Vertical 2PEF-PM cross section of an elementary Lehmann cluster. (D) Lehmann cluster terminating on two particles. (E) Distance vs. time plot for the particle in A shown by solid line and for the particle in B shown by dashed line. (F) A schematic representation of an elementary Lehmann cluster terminating on a particle; the blue and red lines trace the $\lambda^{-1/2}$ and $\lambda^{+1/2}$ defects, respectively.

streak (also called “Lehmann cluster”) has the net Burgers vector equal to zero and is composed of a quadruple of nonsingular λ -disclinations, viz., two $\lambda^{+1/2}$, and two $\lambda^{-1/2}$ disclinations, Fig. 1. Unlike dislocations, Lehmann clusters can terminate on colloidal particles because they have the same number of cholesteric layers on opposite sides and structure compatible with tangential surface anchoring conditions for $\mathbf{n}(\mathbf{r})$ on the colloidal spheres such as the used melamine resin polymer microparticles (see *Materials and Methods* for details). The structures of defect-connected colloids like one shown in Fig. 1 A, B, and D can occur spontaneously during defect coarsening upon quenching the LC cell from isotropic phase. These defect–particle configurations can also be generated using laser tweezers (Movie S1). These defects mediate distance-independent attractive interaction between the particles, with the interaction force equal to the defect line tension (free energy per unit length) (Fig. 1). We measure this force via optical manipulation of a particle attached to the tip of the line defect and tracking its motion, upon being released from the trap, and being dragged at a constant velocity ν (Fig. 1E and Movie S2). Owing to relatively small ν and high effective viscosity η of the LC (i.e., the Reynolds number is small), the inertial forces acting on the particle are negligible. The defect-mediated pair-interaction force F_{int} is balanced by the viscous drag that can be estimated using Stokes’ law, yielding $F_{\text{int}} = F_{\text{viscous}} = 6\pi\eta R\nu$, where R is the particle radius. We use a value of viscosity coefficient that is the average of the measured values for directions parallel and perpendicular to the uniform $\mathbf{n}(\mathbf{r})$, obtaining $\eta = 56.3 \text{ mPa} \cdot \text{s}$ for 5CB-based cholesteric (36). Interactions due to defect lines of zero Burgers vector may involve multiple mobile or stationary particles interconnected by defects. For example, Fig. 1B shows a node of three Lehmann clusters, sustained with their ends pinned to particles. The particle released from a laser trap is dragged by the receding defect with the ensuing force equal to its line tension (Fig. 1E and Movie S3).

The strength of the distance-independent defect-mediated interactions depends on the core structure of oily streaks (Figs. S2–S6). For example, the fragments of optically manipulated Lehmann cluster shown in Fig. 2A turn by $\pm 90^\circ$, so that each part shifts vertically by a distance of $\pm p/4$, to conform to the cholesteric helix. The Lehmann cluster stretched thus metamorphoses into a defect

with a different core structure schematically shown in Fig. 2C, as reconstructed using FCPM vertical cross-sections (Fig. 2D and E). Although the ensuing elastic force acting on this defect-dragged microsphere is also distance-independent, its value is about 1.3–1.4 times larger than for the original Lehmann cluster (Movie S4). Similar study of other oily streaks (Fig. S6) reveals that the strength of defect-mediated colloidal interactions increases with their width. Computer simulations based on minimization of the Frank elastic free energy yield minimum-energy internal structure, line tension, and cross-sectional images of oily streaks consistent with the experiments (Fig. S4 and Table S2). For example, line tension values for the Lehmann cluster in 5CB-based cholesteric obtained by experimental methods range from 17.0 pN to 19.6 pN and the numerical estimate is 20.5 pN.

Lehmann clusters can also “glide” across the layers via “kinks” mediated by winding of the constituent $\lambda^{+1/2}\lambda^{-1/2}$ disclinations (Fig. 3). Fig. 3A shows a Lehmann cluster terminating on a particle and traversing across several layers via kinks such that each winding shifts the cluster across the layers by distance p . In-plane images shown in Fig. 3B–D and cross-sectional images in Fig. 3E–H, obtained in 2PEF-PM imaging mode, show the vertical displacement of the dislocation due to the kink with winding of λ -disclinations. The schematic diagram in Fig. 3I shows reconstructed $\mathbf{n}(\mathbf{r})$ and traces the disclination lines $\lambda^{+1/2}$ and $\lambda^{-1/2}$ that preserve their nonsingular nature by conforming to the cholesteric helix while winding. Both the kink and the colloidal particle weakly pinned to it (with the binding energy approximately $20\text{--}100k_{\text{B}}T$) can be optically translated along the length of the defect (Fig. 3J). Colloidal particles placed at the location of kinks and anti-kinks allow one to affix their positions and prevent their mutual annihilation, thus achieving controlled patterning of colloids and defects in 3D. This shows that the colloidal stabilization of defect structures in cholesteric LCs, originally demonstrated by Zapototsky et al. (20), can be extended down to the level of individual defects and particles. Our experiments indicate that morphing of defect structures between different states typically involves consecutive transformations that preserve the nonsingular nature of defect cores and/or involve low-energy structures that are not separated by elastic

energy barriers. Colloids placed at the nodes and kinks hinder these defect transformations by imposing strong energy barriers $\gg k_B T$ and entrap the system in long-lived metastable states.

Defect-Arbitrated Colloidal Patterning

Elasticity-mediated interactions between defects and particles can be exploited for their 3D patterning. While large particles typically localize at defect nodes (20, 27), colloids of size smaller than the layer thickness exhibit a wide variety of anisotropic interactions with defects and also with each other when confined in defect cores. To explore these interactions, we use melamine resin particles with $R = 1 \mu\text{m}$ and tangential boundary conditions for $\mathbf{n}(\mathbf{r})$, dispersed in a cholesteric LC with $p = 8 \mu\text{m}$. These particles experience highly anisotropic interactions that drive them into well-defined positions within defect cores (Fig. 4) and yield binding potential of the order of $1,000k_B T$. Depending on its initial location, each colloid can stably colocalize with any of the four λ -disclinations forming a Lehmann cluster (Fig. 4 A–D). For example, the attraction of a particle toward the $\lambda^{+1/2}$ disclination is within a range of approximately $4R$ (Fig. 4E), with the distance dependence of the interaction energy shown in Fig. 4F.

Defects and the corresponding director distortions create an elastic potential landscape for the particles to interact while being localized within their cores. The interactions of particles centered on the same λ -disclinations of the core yield binding energies approximately $2,000k_B T$. The particles centered on different disclinations of dislocation or oily streak cores interact to localize roughly in the same plane orthogonal to the defect length (Fig. 4 G and H and Fig. 5 I–K). This can be exploited for self-assembly of various colloidal structures replicating the defect core morphology—e.g., a diamond-like arrangement of four colloids centered on λ -disclination within the Lehmann cluster (Fig. 4G–I). Interestingly, to further minimize elastic energy in this defect-bound colloidal configuration, particles centered at the two $\lambda^{-1/2}$ disclinations get

slightly displaced with respect to each other along the defect length (Fig. 4J), so that only three of the four particles are clearly visible in the cross-sectional images orthogonal to the defect line (Fig. 4 G and H). Two particles embedded in the same λ disclination experience a relatively long-range (up to $\approx 12R$) attractive interaction along the defect line (Fig. 4 E and F).

Glide of dislocations across lamellae via kinks enables colloidal structuring in 3D (Fig. 5 A–D). Although particles centered on the same disclination of an elementary edge dislocation core attract each other along its length (Fig. 5 E and H and Movie S6), they repel from a kink and also from each other when separated by kinks. This behavior is different from the above-discussed attractive interaction between a similar colloid and a vertical winding kink in a Lehmann cluster with nonsingular defect structure (Fig. 3J). The kink in the edge dislocation has length and tilt with respect to lamellae that minimize the overall elastic energy cost of connecting edge dislocation fragments at different layers. When optically moved toward a kink, a particle alters the equilibrium structure, length, and tilt and thus is repelled from it to minimize elastic energy. The magnitude of interaction potential is of the order of $1,000k_B T$ at short distances. Therefore, these interactions can be employed to selectively arrange colloids at different height across lamellae while being centered at the $\tau^{\pm 1/2}$ or $\lambda^{\pm 1/2}$ lines. For example, particles embedded in the same elementary dislocation and separated by kinks form a sparsely spaced ladder-like structure shown in Fig. 5 B–D. The sequence of vertical cross-sections (Fig. 5D) demonstrates how the $b = p/2$ dislocation core alternates between that composed of $\tau^{-1/2}\lambda^{+1/2}$ and $\lambda^{-1/2}\tau^{+1/2}$ disclinations (Fig. 5 F and G) and how particles find well-defined equilibrium positions while interacting with each other and kinks within the core. Dislocations and oily streaks can be optically manipulated to induce kinks and thus generate a desired profile of elastic potential along their lengths, both within and across the layers. For example, the kink/anti-kink pair in the dislocation of Burgers

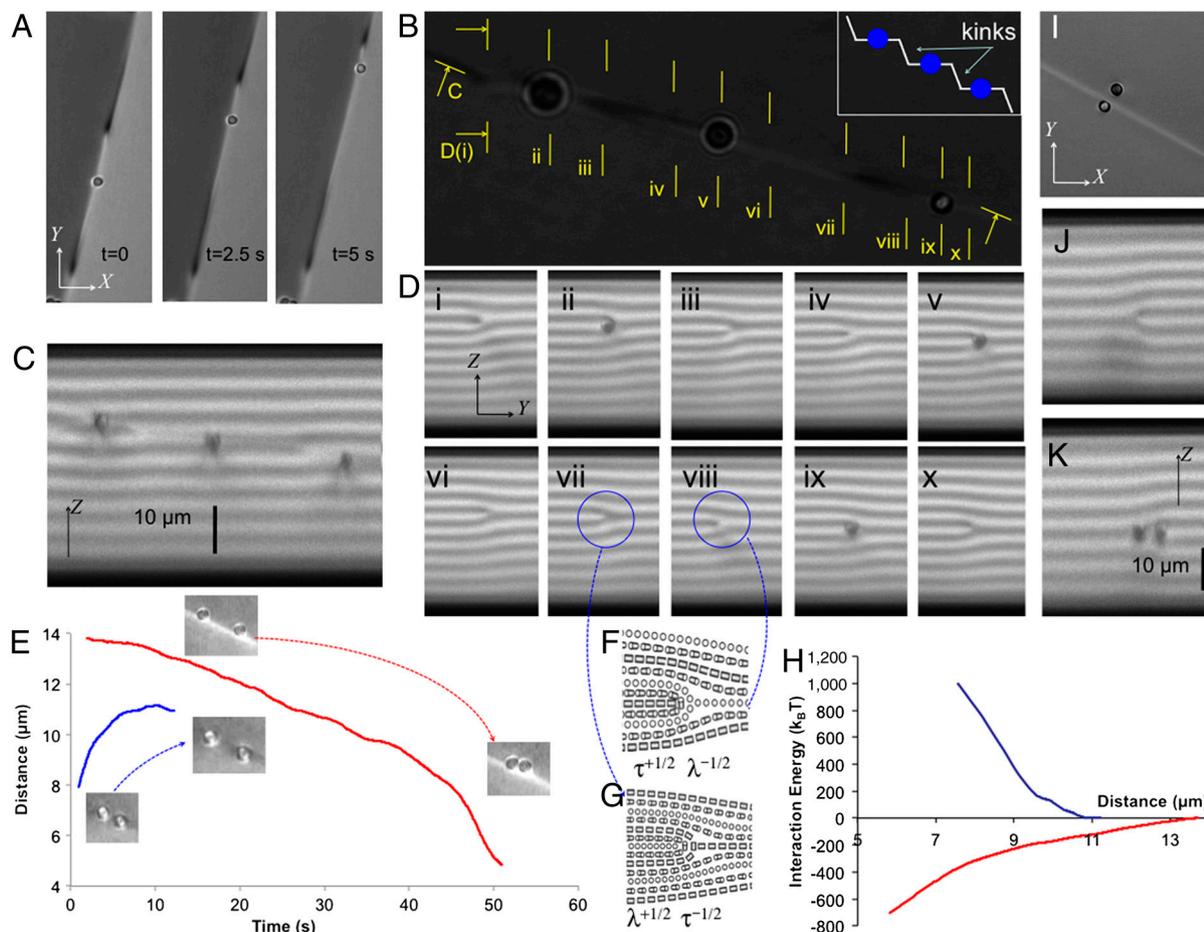

Fig. 5. Three-dimensional patterning of particles along edge dislocations with kinks. (A) Lateral manipulation of a kink in an edge dislocation using an optically trapped particle. (B) In-plane image showing particles embedded within an edge dislocation and separated by kinks; the inset schematically shows how colloidal particles localize on edge dislocations at different depths within the layered system while separated by kinks. (C) Vertical FCPM cross-section along the length of an edge dislocation as marked in B. (D) A series of vertical FCPM cross-sections in planes perpendicular to the dislocation as marked in B. (E) Distance vs. time plot describing the motion of interacting particles embedded into the dislocation: The particles repel from each other (blue curve) when separated by a kink but mutually attract (red curve) without kinks. The initial and final positions of the particles are shown in the insets for both cases. (F and G) Schematics of two alternating core structures of the $b = p/2$ dislocation as it shifts vertically to form kinks. (H) The distance dependence of the interaction energy for both the repulsive (blue) and the attractive (red) interparticle interactions within the edge dislocation with and without separating kinks, respectively. (I) Planar and (J and K) vertical cross-sections of particles arranged in a dipolar fashion within the core of a $b = p/2$ dislocation.

vector $b = p/2$ shown in Fig. 5A is generated using optical tweezers acting on a pinned particle as shown in Fig. S7.[†] The axial optical trapping force needed to generate the kinks of $b = p/2$ dislocation via pulling or pushing colloidal particles across the layers is of the order of 10–15 pN, in agreement with the estimates of the Peierls–Nabarro friction due to the transformation between $\tau^{-1/2}\lambda^{+1/2}$ and $\lambda^{-1/2}\tau^{+1/2}$ disclination pairs in the core (6). The kink can be optically translated along the defect length (Fig. 5A), and their position can be affixed by use of particles larger than the lamellar size, as discussed above. Thus, the linear defects can be directed along a desired 3D path within and across lamellae, giving rise to the desired landscape of interaction potential for patterning of sublamellar-sized particles.

Discussion

Most colloidal self-assembly approaches rely on the formation of close-packed crystal structures, taking advantage of typically

short-range screened electrostatic and other interactions (1). We have demonstrated sparsely spaced controlled arrangements of colloids in cholesteric lamellae that utilize reconfigurable elastic interactions enriched by defects and stabilized by strong energy barriers for transformation and annihilation of defects caused by presence of particles. The nature of interactions and the intradefect assemblies are scale-invariant and hence can be controlled by changing the cholesteric pitch from about 50 nm to hundreds of microns. Because the defect structures and elasticity in other lamellar systems are similar to the ones studied here, our approach of using defects for sparse arrangement of colloids can be extended to other lamellar hosts such as diblock copolymers, DNA condensates, and various smectic LCs, as long as the energetic barriers due to the transformation of particle-stabilized defect structures can be kept $\gg k_B T$. Importantly, because the observed behavior of colloids in this system only depends on the boundary conditions for $\mathbf{n}(\mathbf{r})$ at their surfaces, one can use particles of different material compositions, including metal plasmonic nanoparticles. Stable self-assembled arrangements of elastically bound two, four, or more particles centered in disclinations of the cores of dislocation and oily streaks are thus of great interest for applications such as nanoantennas and optical field concentrators, especially because the interparticle spacing can be varied from nanometers to microns. In addition to laser tweezers,

[†]Inducing glide of $b = p$ dislocations requires transformation of the $\lambda^{-1/2}\lambda^{+1/2}$ non-singular disclination pair into a pair of singular $\tau^{-1/2}\tau^{+1/2}$ disclinations. The core energy increase under the transformation is approximately $pK \ln(p/r_c)$, where r_c is the size of the singular core. For ZLI-2806 with $K \approx 12$ pN, one finds that the required force would be >100 pN, larger than the maximum axial trapping force value that can be exerted by the used optical traps. This explains why only the $b = p/2$ but not the $b = p$ dislocations can be optically shifted across layers via kinks.

the control of the 3D defect–particle architectures can be based on the application of electric fields, by using electrophoretic/dielectrophoretic forces applied to particles or through the modification of defect core structures due to direct coupling of $\mathbf{n}(\mathbf{r})$ with applied fields; using LCs with positive or negative dielectric anisotropy further enriches the control capabilities. The former approach offers tuning of line tension of linear defects like oily streaks (allowing one to even achieve negative tension values in materials with positive dielectric anisotropy), providing additional robust means for tuning interactions between particles at the ends of connecting defects or within the defect cores. Magnetic control can be efficient when using ferromagnetic or superparamagnetic colloids (37). One can expect that observed interactions would be highly dependent on the shape of used particles (38), possibly enabling selective shape-dependent localization of particles into different disclinations within the defect cores.

Conclusions

We have demonstrated 3D patterning of defect–colloidal networks in cholesteric lamellae by using optical generation and stabilization of desired defect structures by means of colloids. The stabilized defect networks, in turn, form a 3D elastic energy landscape capable of entrapping sublamellar-sized colloids. By introducing kinks in dislocations and oily streaks, interactions between these smaller colloids can be tuned from attractive to repulsive, offering powerful means to control sparsely spaced colloidal assemblies. Because both dielectric and metal particles can be used to form these defect–colloidal structures, potential applications include engineering of new structured materials, optical nanoantennas, and metamaterials. Acting as elastic “bonds” connecting particles in long-lived metastable states, these highly controlled defect networks also offer the means to design elastic properties of new LC–colloidal composites (20, 21, 39).

Materials and Methods

Cholesterics are prepared by mixing nematic LCs 4-Cyano-4'-pentylbiphenyl (5CB) or ZLI-2806 with a chiral dopant CB15 (all from EM Chemicals). The value of the pitch p is set by choosing concentration of the chiral dopant (C_{chiral}) of known helical twisting power h_{HTP} (Table S1), so that $p = 1/(h_{\text{HTP}} \times C_{\text{chiral}})$. For FCPM and 2PEF-PM, the LCs are doped with a small amount (0.05 wt%) of anisotropic dye n, n' -bis(2,5-di-tert-butylphenyl)-3,4,9,10-perylene-dicarboximide (BTBP, Aldrich). We have used melamine resin particles of 2 and 4 μm in diameter. These particles set tangential boundary conditions for $\mathbf{n}(\mathbf{r})$ on their surface. We first obtain the particles in a powder form from an aqueous dispersion (from Aldrich) by evaporating water. The particles are then dispersed in the LC and the resultant mixture is sonicated to break particle aggregates. LC cells are made with two glass substrates of thickness 0.15 mm, as required by imaging and optical trapping with high-numerical-aperture objectives. Strong planar surface anchoring boundary conditions are set by spin-coating and curing a thin layer of polyimide PI-2555 (HD Micro-Systems), and then unidirectionally rubbing it with a piece of velvet cloth to define the alignment direction. The thickness of LC cells is set to 30–60 μm by sandwiching the glass substrates with silica microspheres of corresponding size. The LC is infiltrated into the cells by use of capillary forces.

Optical manipulation and 3D imaging is performed with an integrated setup composed of holographic optical tweezers and multimodal imaging that includes FCPM and 2PEF-PM (see *SI Text* and *Fig. S1*). The use of two different 3D imaging techniques allows us to assure that various artifacts, such as the Mauguin following of light polarization in the twisted structures, do not affect the reconstruction of the $\mathbf{n}(\mathbf{r})$ -structures. The defect tension is measured by several different approaches with the use of colloidal particles as “handles” and without them, all yielding consistent results described in details in the supporting material. Particle motion is tracked by videomicroscopy at 15 frames per second using a charge coupled device camera.
